

Mast Cells Are Key Mediators of Cathelicidin-Initiated Skin Inflammation in Rosacea

Yumiko Muto¹, Zhenping Wang¹, Matthieu Vanderberghe¹, Aimee Two¹, Richard L. Gallo¹ and Anna Di Nardo¹

Rosacea is a chronic inflammatory skin disease whose pathophysiological mechanism is still unclear. However, it is known that mast cell (MC) numbers are increased in the dermis of rosacea patients. MC proteases not only recruit other immune cells, which amplify the inflammatory response, but also cause vasodilation and angiogenesis. MCs are also one of the primary sources of cathelicidin LL-37 (Cath LL-37), an antimicrobial peptide that has been shown to be an enabler of rosacea pathogenesis. Here, we demonstrate that MCs are key mediators of cathelicidin-initiated skin inflammation. After Cath LL-37 injection into the dermis, MC-deficient *B6.Cg-Kit^{W-sh}/HNIhrJaeBsmJ* (*Kit^{W-sh}*) mice did not develop rosacea-like features. Conversely, chymase ($P < 0.001$), tryptase, and *Mmp9* ($P < 0.01$) mRNA levels were significantly higher in C57BL/6 wild-type (WT) mice. Treating WT mice with an MC stabilizer significantly decreased the expressions of *Mmp9* and *Cxcl2* ($P < 0.01$). Our data were confirmed on erythematotelangiectatic rosacea subjects who showed a decrease in matrix metalloproteinase activity ($P < 0.05$), after 8 weeks of topical cromolyn treatment. We conclude that MCs have a central role in the development of inflammation subsequent to Cath LL-37 activation and that downregulation of activated MCs may be a therapy for rosacea treatment.

Journal of Investigative Dermatology (2014) **134**, 2728–2736; doi:10.1038/jid.2014.222; published online 26 June 2014

INTRODUCTION

Rosacea is a chronic inflammatory skin disease that affects ~16 million Americans (The National Rosacea Society, <http://www.rosacea.org/>). Flares often occur without specific triggers, and when left untreated they can take weeks to subside (Scharschmidt *et al.*, 2010). The formation of an aberrant form of antimicrobial peptide, cathelicidin LL-37 (Cath LL-37), on the surface of the skin has been previously implicated as a key initiator of rosacea (Yamasaki *et al.*, 2007). Cath LL-37 in the skin is also implicated in a wide range of inflammatory diseases including atopic dermatitis (Ong *et al.*, 2002) and psoriasis (Lande *et al.*, 2007). The active form of cathelicidin LL-37 peptide is not only able to kill microbes but is also able to modify host immunity and growth responses by promoting leukocyte chemotaxis (De *et al.*, 2000) and angiogenesis (Koczulla *et al.*, 2003), and it can alter the expression of extracellular matrix components (Park *et al.*, 2009). In rosacea, the formation of an aberrant form of Cath LL-37 on the surface of the skin has been attributed to the

overactivity of the kallikrein-related peptidases (KLKs), which are a family of tryptic serine proteases that are responsible for generating Cath LL-37 from its precursor protein, hCAP18, in the epidermis (Yamasaki *et al.*, 2007; Yamasaki and Gallo, 2008). In an animal model, intradermal injection of Cath LL-37, but not mouse cathelicidin, induced an inflammatory response with rosacea-like features (Yamasaki *et al.*, 2007). Interestingly, subantimicrobial doses (40 mg per day) of doxycycline, a proven treatment for human rosacea, directly inhibits matrix metalloproteinases (MMPs), which in turn inhibits the activity of KLKs and prevents the activation of cathelicidins in human epidermal keratinocytes (Korting and Schollmann, 2009; Kanada *et al.*, 2012). Therefore, Cath LL-37 has emerged as a key mediator in the pathogenesis of rosacea.

Many studies have proven that mast cells (MCs) are able to enhance host defense through direct effects on pathogens by initiating the inflammation associated with innate immune responses (Galli *et al.*, 2008). Although MCs can contribute to overall host protection by releasing a variety of molecules, including tumor necrosis factor- α (McLachlan *et al.*, 2008), leukotriene B₄ (Malaviya and Abraham, 2000), and cathelicidin AMP (Di Nardo *et al.*, 2003), accumulated studies have also specifically implicated MCs in the development of inflammation in the skin (Thurmond *et al.*, 2008; Kawakami *et al.*, 2009; Lin *et al.*, 2011). Most importantly, in the context of our study, MCs have been observed in increased numbers in the skin lesions of rosacea patients. Until now, however, there has been no clear proof of the direct connection between MCs and rosacea formation.

In addition to inflammation, neuronal dysregulation is equally important to rosacea pathogenesis. In fact, neuronal dysregulation contributes to the disease via various mechanisms, such as vasomotor instability, release of proinflammatory neuropeptides (NPs), and neuronal injury (Roosterman *et al.*, 2006; Wang *et al.*, 2008). MCs can also be activated by NPs to release their components upon cell degranulation. NPs have also been shown to induce the production of tumor necrosis factor- α , CCL2, CCL5, CXCL9, CXCL10, and CXCL8 in human MCs (Kulka *et al.*, 2008), which leads to the recruitment of dendritic cells/macrophages (via CCL2), TH1 lymphocytes (via CCL5, CXCL9, or CXCL10), and neutrophils (via CXCL8) (Gangavarapu *et al.*, 2012). In the current study, we show that NPs induce MC enzyme activation and subsequent Cath LL-37 generation from hCAP18. On the basis of these results, it is likely that MCs are mediators of the stress-response network in skin inflammation (Arck *et al.*, 2006). Considering previous studies of the role of MCs in rosacea, we propose that MCs and MC proteases have critical functions during the development of skin inflammation in rosacea. Furthermore, understanding the *in vivo* connections between MCs, epidermal keratinocytes, and sensory nerves, respectively, may lead to a better interpretation of the pathophysiology of rosacea.

RESULTS

MC-deficient mice do not develop inflammation following Cath LL-37 injection in the skin

To verify that MC proteases are increased in rosacea skin, biopsies from six rosacea patients and six healthy control volunteers were collected and *CMA1* (chymase gene) and *MMP9* (metalloprotease 9 gene) mRNA expressions were measured as essential markers of MC presence and activation (Tchougounova *et al.*, 2005). Both *CMA1* and *MMP9* mRNA levels showed significant increases in rosacea skin ($n=6$) compared with healthy skin ($n=6$) (Figure 1a).

This means that MCs were abnormally activated and were specifically expressing enzymes involved in Cath LL-37 processing.

To prove that MCs are central to the pathogenesis of rosacea inflammation, we used a well-established mouse model of rosacea-like inflammation (Yamasaki *et al.*, 2007). We injected Cath LL-37 intradermally into MC-deficient mice *B6.Cg-Kit^{W-sh}/HNIhrJaeBsmJ* (*KitW-sh*) and compared the resulting inflammation with wild-type (WT) mice. Our clinical endpoint observation (at 72 hours) showed, as previously described, inflammation in the skin of WT mice injected with Cath LL-37, whereas *KitW-sh* mice did not develop any rosacea-like features (Figure 1b). To further establish the essential role of MCs in the observed phenotype, we reconstituted the MC-deficient mice with WT MCs and repeated the injections with Cath LL-37. To define the specificity of Cath LL-37 in MC activation, we also included a Cath LL-37 scrambled peptide in the experiments. Our results showed that, after Cath LL-37 challenge, *Mmp9* mRNA expression in skin from MC-deficient mice was significantly lower than in skin from WT ($P<0.01$) and WT MC-reconstituted *KitW-sh* mice ($P<0.05$). There was no significant

difference observed between any of the mouse groups when Cath LL-37 scrambled peptide was used (Figure 1c). We also injected different concentrations (50 and 320 μ M) of Cath LL-37 peptide into WT mice and demonstrated that Cath LL-37 induced an increase in MMP activity in a dose-dependent manner in WT mice (Figure 1d). Furthermore, a time-course experiment showed that mRNA of the MC-specific proteases chymase and tryptase were expressed immediately after injection of Cath LL-37, whereas the same enzymes were not detectable in the skin of the MC-deficient mice (Figure 1e).

Mouse MCs (mMCs) release MMP-9 and IL-6 in response to Cath LL-37

To confirm that MCs are responsive to direct Cath LL-37 stimulation, bone marrow-derived mouse MCs (mMCs) were stimulated with different concentrations of Cath LL-37 at different time points. *Mmp9*, *Cma1* (the gene for Chymase), and *Tpsab1* (the gene for Tryptase) mRNA expressions were significantly higher at 5 hours ($P<0.001$; Figure 2a), whereas *Mmp1a*, *Ilk5*, and *Ilk6* were not detectable at 5 hours (data not shown). There were no differences in *MMP9*, *Cma1*, and *Tpsab1* mRNA expressions with different Cath LL-37 concentrations at 24 hours (data not shown). MMP-9 protease activity in the culture medium of MCs stimulated with Cath LL-37 for 24 hours was confirmed by fluorescence enzymatic activity assay using an MMP-specific substrate and an MMP-9-specific inhibitor (Figure 2b). In Figure 2b, the difference between the two curves indicates MMP-9-specific activity. MC degranulation was confirmed by measuring β -hexosaminidase release in Cath LL-37-stimulated MC supernatants. We also found that a very low concentration of Cath LL-37 (20 nM) was enough to induce degranulation (Figure 2c). In addition, ELISA detected high levels of secreted IL-6 in mMCs after 24 and 48 hours of stimulation with different Cath LL-37 concentrations (20 and 40 nM; Figure 2d). IL-6 increase was also confirmed *in vivo*. In fact, *Il6* mRNA expression was also observed in the skin from WT mice, but not in MC-deficient mice, after Cath LL-37 challenge (Figure 2e).

NPs activate tryptic-MC serine proteases in WT mouse skin

Rosacea flare-ups are frequently initiated by face flushing due to neuronal dysfunction and increased release of pituitary adenylate cyclase-activating peptide (PACAP; Schwab *et al.*, 2011). To investigate whether NPs require MC activation for the development of the inflammatory response in rosacea, 100 μ l of 1 μ M NPs (substance P: SP; adrenomedullin-2: ADM-2; Pituitary adenylate cyclase-activating peptide: PACAP) were injected intradermally into WT and MC-deficient mice. After 6 hours from the NP challenge, skin biopsies were taken and processed for mRNA expression analysis. Tryptase mRNA expression was observed to be markedly increased by PACAP stimulation ($P<0.01$) in WT mice. *Cma1*, *Tpsab1*, *Mmp1a*, and *Mmp9* were also significantly increased ($P<0.05$) in WT mice (Figure 2f), but not as substantially as PACAP. In addition, mRNA expressions of the proinflammatory cytokines *Cxcl2* (mouse homolog of human *IL8*) and *Tnf* (gene for tumor necrosis factor- α) were also significantly increased with

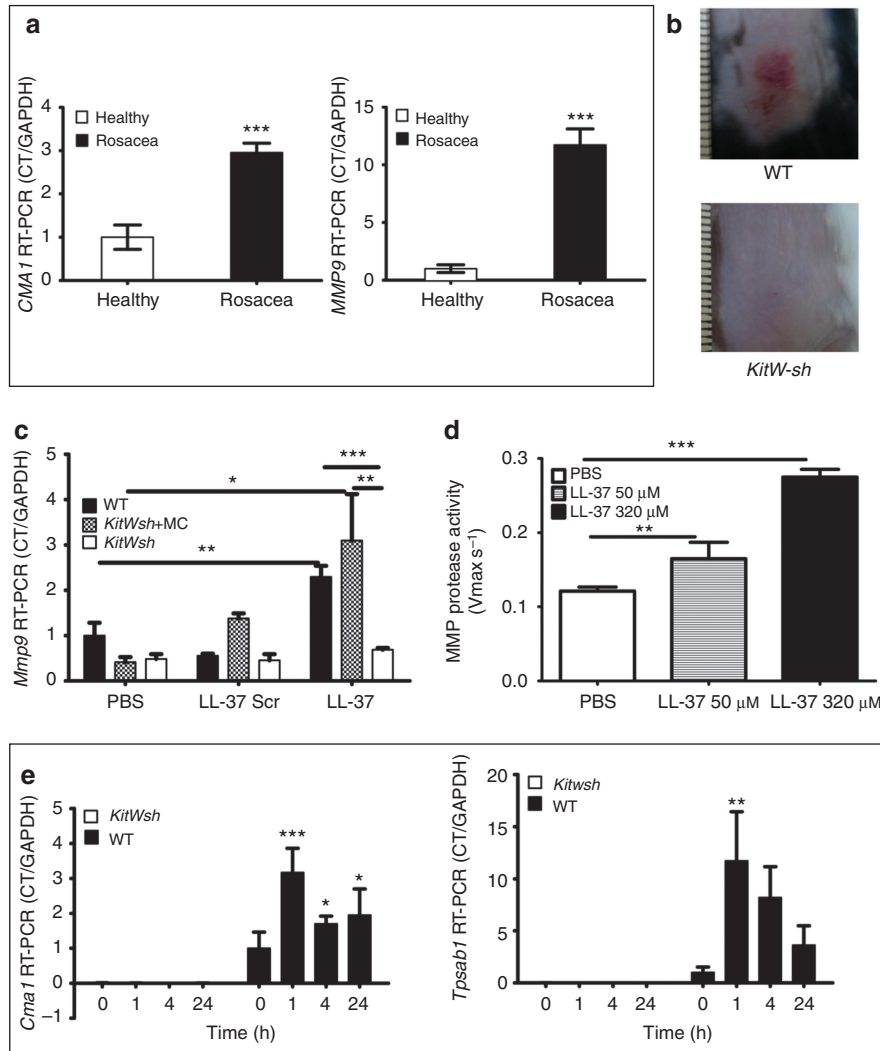

Figure 1. Mast cell (MC) proteases and MMP-9 are crucial for rosacea inflammation development. (a) Human biopsy samples from healthy subjects ($n=6$) and rosacea subjects ($n=6$) were assessed for *CMA1* and *MMP9* mRNA expressions. (b) The back skins of wild-type C57BL/6 (WT) and MC-deficient (*KitW-sh*) mice were injected intradermally with Cath LL-37. Pictures were taken 72 hours after LL-37 injections. (c) Reverse transcriptase-PCR (RT-PCR) of *Mmp9* mRNA expression in skin biopsies from WT, WT MC-reconstituted *KitW-sh* (KitWsh), and *KitW-sh*. Mouse skin was injected with LL-37, LL-37 scrambled peptide (LL-37 Scr), or PBS control (PBS) and harvested after 72 hours of observation. (d) Assessment of MMP protease activity in WT mouse skin after challenge with PBS or Cath LL-37 at 50 and 320 μM . (e) Mouse Chymase (*Cma1*) and mouse Tryptase (*Tpsab1*) were analyzed by RT-PCR in the skin from WT or *KitW-sh* mice (KitWsh) at 0, 1, 4, and 24 hours after Cath LL-37 challenge. All of the experiments were repeated at least three times. Statistics: Mann-Whitney test, one-way analysis of variance, and two-way analysis of variance. * $P<0.05$, ** $P<0.01$, *** $P<0.001$ ($n=3$). MMP, matrix metalloproteinase.

PACAP challenge in WT mice, but not in MC-deficient mice ($P<0.01$; Figure 2g). These results prove that neurovascular alteration and neuropeptide release during a face flushing can be translated to rosacea inflammation in skin through the activation of MC enzymes. Moreover, these same MC enzymes can further increase the levels of free Cath LL-37 and amplify the inflammatory response.

MC stabilizer suppresses the development of rosacea-like inflammation *in vivo*

According to the obtained results, MC proteases and MMP-9, which are released from MCs upon stimulation by Cath LL-37,

are central in promoting rosacea-like skin inflammation. Therefore, we anticipated that blocking MC degranulation would also prevent the formation of rosacea-like inflammation in the skin. To test this hypothesis, cromolyn sodium, a very well known MC stabilizer, was injected intraperitoneally into WT mice (10 mg kg^{-1} body weight, per day) for 4 days before Cath LL-37 challenge. At 24 hours after the last cromolyn sodium injection, mice were injected with 50 μl of 320 μM Cath LL-37 or phosphate-buffered saline (PBS) twice a day for 2 days. As expected, skin inflammation did not develop in the mice pretreated with cromolyn. *Mmp9* and *Cxcl2* expressions were significantly decreased in the cromolyn-treated mice

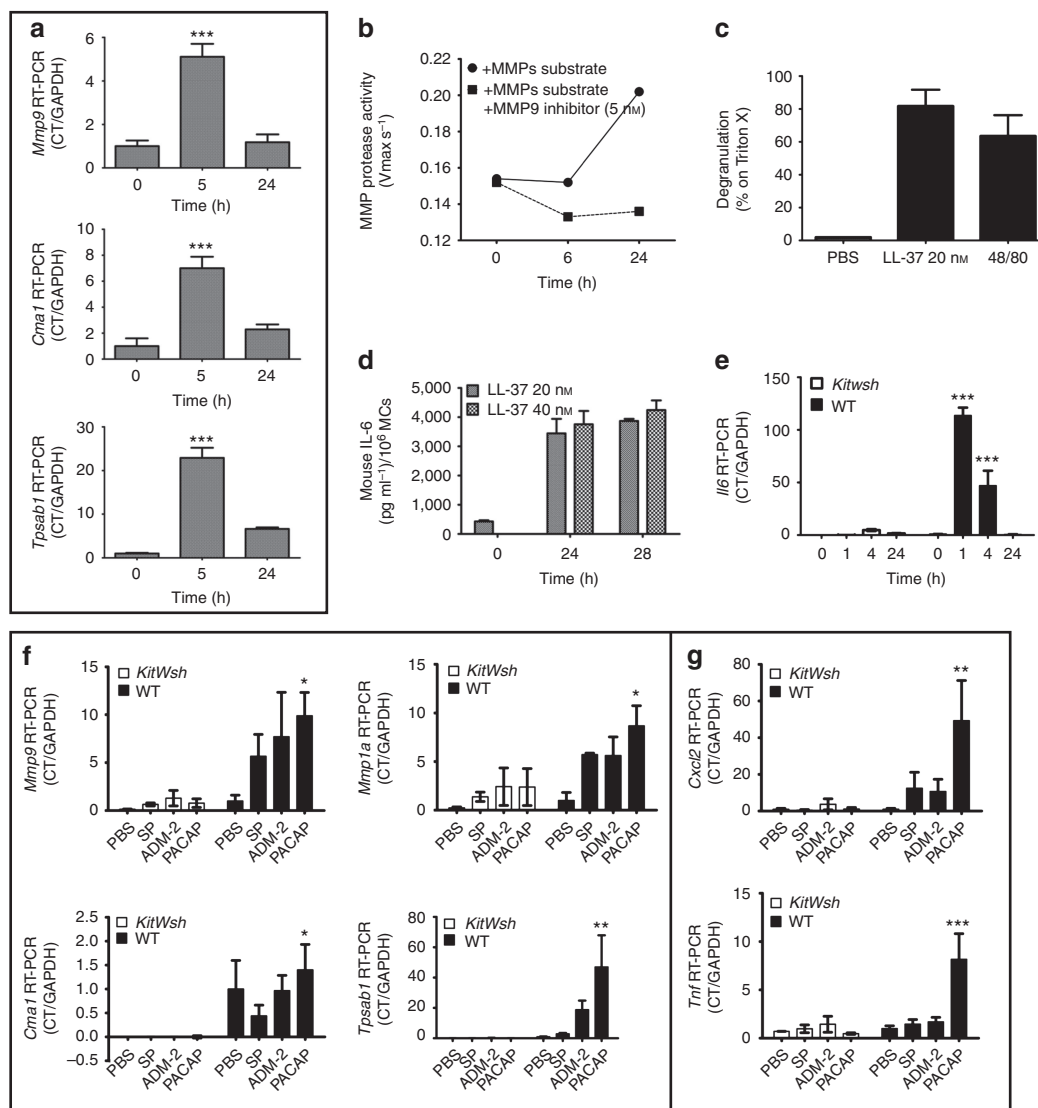

Figure 2. Cathelicidin and neuropeptide pro-inflammatory activities are dependent on mast cell (MC) protease. (a–e) Cath LL-37 induces proinflammatory responses. (a) *In vitro* mMCs expression of Metalloprotease 9 (*Mmp9*), Chymase (*Cma1*), and Tryptase (*Tpsab1*) after Cath LL-37 stimulation. (b) mMC Metalloprotease activity (MMP protease activity) after Cath LL-37 challenge. (c) mMC degranulation (as β hexosaminidase release) in response to 24 hours of treatment with 20 nM LL-37, positive control (48/80), and negative control (PBS). (d) ELISA IL-6 level (as pg ml⁻¹ per million MCs) in mMC culture 24 and 48 hours after 20 and 40 nM LL-37 treatment. (e) *In vivo* *Il6* mRNA expression in mouse skin after 0, 1, 4, and 24 hours of Cath LL-37 challenge in WT- and MC-deficient mice (*KitWsh*). (f–g) Neuropeptide-induced proinflammatory cytokine expression in skin is decreased in the absence of MCs in *KitWsh* mice. WT and *KitWsh* (*KitWsh*) mice were injected with PBS or neuropeptide (SP, substance P; ADM-2, adrenomedullin-2; PACAP, pituitary adenylate cyclase-activating peptide) intradermally. (f) mRNA expressions of mouse Chymase (*Cma1*), mouse Tryptase (*Tpsab1*), mouse metalloprotease 9 (*Mmp9*), and metalloprotease 1 (*Mmp1a*) after NP challenge. (g) mRNA expressions of proinflammatory cytokines (*Cxcl2* and *Tnf*) after NP challenge. Statistics: two-way analysis of variance. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ ($n = 3$) repeated three times. mMC, mouse mast cell; NP, neuropeptides; WT, wild-type.

($P < 0.01$; Figure 3a). Consistent with *Mmp9* mRNA expression, MMP activity in the tissue was also markedly decreased by cromolyn pretreatment ($P < 0.01$; Figure 3b). In addition, frozen skin sections were stained with anti-MMP-9 and anti-Fc ϵ RI antibodies for the detection of MCs. The immunostaining images showed that numerous MMP-9-positive MCs were observed in Cath LL-37-treated mice, but not in cromolyn-pretreated Cath LL-37 mice (Figure 3c left panel versus right panel).

Human MC (huMC) proteases increase keratinocyte expression of LL-37

Because we wanted to understand how human keratinocytes respond to human MCs (huMCs), we examined a coculture of normal human epidermal keratinocyte (NHEK) cells with supernatant from huMCs, which had been degranulated by compound 48/80. MMP and KLK enzyme activities were significantly increased in NHEK cells when the cells were cocultured for 24 hours with 100 μ l of huMC supernatant

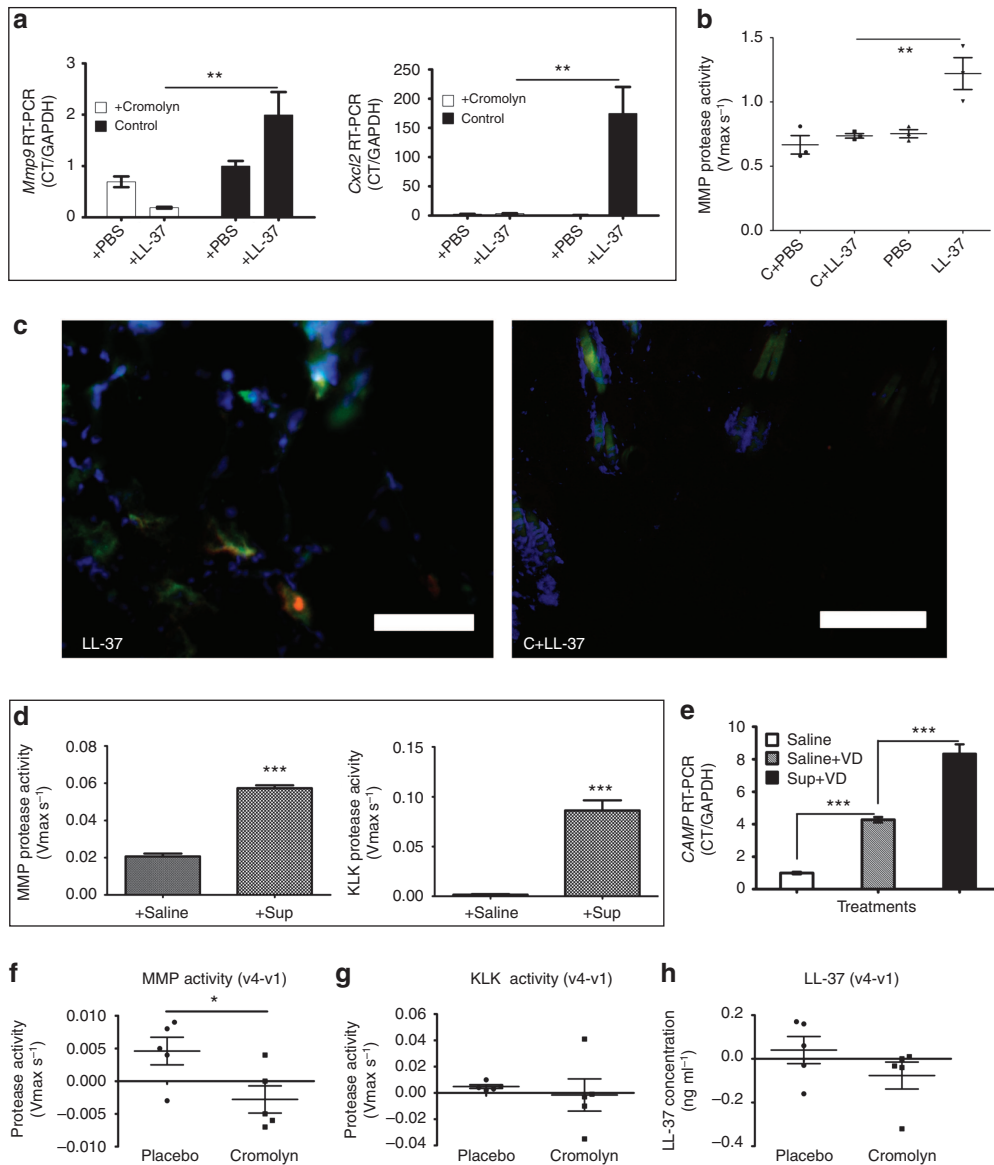

Figure 3. Mast cell (MC) stabilizer suppresses the development of rosacea-like inflammation. (a–c) Cromolyn treatment of the rosacea mouse model. Mice were treated with cromolyn (C) or cromolyn and LL-37 (C + LL-37). (a) Skin mRNA expression of mouse metalloproteinase 9 (*Mmp9*) and proinflammatory cytokine (*Cxcl2*). (b) Skin Metalloproteinase total activity (MMP activity). (c) Mouse skin immunohistochemistry of mMC-MMP9 contents after LL-37 challenge (left image, LL-37) and cromolyn pretreatment LL-37 challenge (right image, C + LL-37). MMP-9 (green), FcεRI (red: MC marker), and 4', 6-diamidino-2-phenylindole (blue: cell nuclei). Yellow–orange hue indicates MMP9 and mMC colocalization. Yellow–orange color is not present in the right image. Scale bar = 50.0 μm. (d, e) MC degranulation increases protease activity in NHEKs. (d) MMP and KLK protease activities in NHEKs after addition of the product of huMC degranulation in saline buffer (+Sup), or saline buffer (+Saline). (e) Reverse transcriptase–PCR Cath LL-37 mRNA (*CAMP*) expression in NHEK cells treated with the product of huMC degranulation in saline buffer and 1,25(OH)₂VD₃ (Sup + VD), or saline buffer and 1,25(OH)₂VD₃ (Saline + VD), and saline alone (Saline). (f–h) Cromolyn effect on protease activity of rosacea patients. (f) MMP activity on the skin of patients treated with placebo (n = 5) or cromolyn (n = 5). (g) KLK activity. (h) LL-37 peptide level. Statistics: ****P* < 0.001, ***P* < 0.01, **P* < 0.05. huMC, human mast cell; KLK, kallikrein; mMC, mouse mast cell; MMP, matrix metalloproteinase; NHEK, normal human epidermal keratinocyte.

(*P* < 0.001; Figure 3d). As the activation of cathelicidin in keratinocytes requires the active form of vitamin D₃, 1,25(OH)₂VD₃ (Schauber *et al.*, 2007), we also added 1,25(OH)₂VD₃ in the coculture model. The Cath LL-37 mRNA (*CAMP*) level was significantly increased after coculture with huMC supernatant (*P* < 0.001; Figure 3e).

Therefore, this confirms that, although LL-37 activates MCs, MC supernatants increase protease production in human

skin epidermis, amplifying the inflammation and creating a vicious cycle.

Stabilization of MCs could be a target therapy for erythematotelangiectatic rosacea

To test whether our results were relevant in humans, 10 randomized adults with erythematotelangiectatic rosacea were chosen to apply a solution containing either the MC

stabilizer (4% cromolyn sodium) or placebo, topically to their face, twice daily. Six tape strips were obtained from both right and left cheeks, at the time of first visit (v1) and last visit (v4). Facial erythema was clinically assessed by a blind investigator using the Clinician's Erythema Assessment (CEA). None of the subjects presented with papules and pustules; therefore, after 8 weeks (v4), only facial erythema levels decreased in the cromolyn treatment group (data not shown). MMP activity was significantly decreased in the cromolyn treatment group (Figure 3f), whereas KLK activity (Figure 3g) and Cath LL-37 protein levels (Figure 3h) only showed a mild decrease.

DISCUSSION

An abnormal increase in the free form of hCAP18 (Cath LL-37) antimicrobial peptide in human skin is crucial for the pathogenesis of rosacea (Yamasaki *et al.*, 2007). MCs are one of the primary sources of cathelicidin in the skin, and they are also the main source of enzymes that activate cathelicidin to its active form (Cath LL-37; Di Nardo *et al.*, 2003). Previous studies have reported that MC activity increases in the skin of rosacea patients (Yamasaki *et al.*, 2007). However, a great number of questions remain regarding the manner in which inflammatory signals are transmitted from the epidermis to vessels and inflammatory cells. In the present study, we found that MC proteases and *Mmp9* mRNAs are highly expressed in skin from rosacea patients (Figure 1a). Therefore, we hypothesize that after Cath LL-37 has been released from the epidermis in rosacea skin it in turn activates MCs to induce inflammation and neutrophil recruitment, which results in more Cath LL-37.

We next demonstrated that Cath LL-37 peptide strongly activates skin MCs to release proteases that are crucial in the development of rosacea-like inflammation *in vivo*. We clearly showed that in MC-deficient mice intradermal Cath LL-37 injections did not generate all of the dermal events that are usually found in rosacea, including inflammation and MMP-9 activation. To more strongly support our hypothesis that MCs are crucial in the generation of skin inflammation, we also reconstituted MC-deficient mice with WT MCs and showed that the rosacea-like inflammation phenotype reappears. Moreover, we demonstrated the specificity of Cath LL-37 peptide in MC activation by showing that injection of a scrambled peptide did not induce inflammation (Figure 1c). This result is nicely paralleled by our *in vitro* experiments, where we observed an increase in MMP-9 protease activity in the culture supernatant of Cath LL-37-treated mMCs (Figure 2b). Our hypothesis that MMP-9 is involved in rosacea pathogenesis is supported by the recent discovery that doxycycline, which is an effective therapeutic for improving rosacea symptoms, inhibits MMPs directly (Kanada *et al.*, 2012).

Any signal (especially from neurogenic factors) that induces the activation of MCs results in the amplification of the inflammatory response, and thus we propose that MCs are the missing link between flaring and inflammation in rosacea. Trypsin activates PAR-2 on nerve endings and keratinocytes, which in turn causes the release of NPs (Steinhoff *et al.*, 1999). On the other hand, activated PAR-2 stimulates MC mediator release (eg, histamine release) during cutaneous inflammation

(Aubdool and Brain, 2011). Transient receptor potential vanilloid 1 (TRPV1) and ankyrin 1 (TRPA1), which are highly expressed on primary sensory neuron endings, are also strongly present in rosacea skin (Aubdool and Brain, 2011). Activated PAR-2 enhances these receptors in the vascular endothelial cells and immune cells (Aubdool and Brain, 2011), explaining how MCs might be linked to rosacea flushing and erythema. PACAP is a neuropeptide that has been shown to be one of the main mediators in the response to psychological stress and is abundantly expressed in rosacea-affected skin (Schwab *et al.*, 2011). It has been reported that PACAP is not only able to induce neuronal inflammation, but also edema and flushing in human skin (Roosterman *et al.*, 2006). Our *in vivo* experiments have proven that intradermal injections of PACAP significantly induce the expression of the MC proteases, *Mmp1a*, and *Mmp9* in WT mice but not in MC-deficient mice (Figure 2f). Moreover, markedly increased expressions of the proinflammatory cytokines *Tnf* and *Cxcl2* were observed in skin after PACAP challenge (Figure 2g). Although it is well known that neuronal activation results in the release of MC-derived histamine and leukotriene, our study also confirms that PACAP increases the expressions of *Mmp1* and *Mmp9*, which are activators of hCAP18 processing to Cath LL-37. In our last experiment, we also proved that activated MCs release enzymes that increase LL-37 expression in keratinocytes. Therefore, we have proven a link between PACAP and Cath LL-37. Consequently, these peptides work synergistically in the development of rosacea symptoms in human skin.

As MC activation has an important role in rosacea inflammation, we examined whether the stabilization of MCs can directly reduce skin inflammation in WT mice. In our research, mice injected intraperitoneally with cromolyn did not develop rosacea-like skin inflammation after Cath LL-37 challenge. Moreover, MMP activity, *Mmp9* and *Cxcl2* mRNA expressions, and MMP-9/MC immunostaining in the skin were significantly decreased compared with mice not treated with cromolyn. *Cxcl2* is the mouse homolog of human *IL8* and is crucial for neutrophil recruitment *in vivo*.

Few case reports have cited MC stabilizers as a potential treatment for rosacea and Morbus Morbihan (Hu *et al.*, 2012); however, we have now determined that MC stabilizers actually block MC-induced inflammation and have the potential to be developed as therapeutics for the treatment of rosacea. Skin MCs are localized near keratinocytes and sensory nerve endings in the epidermis and dermis; therefore, MC proteases (chymase and trypsin), histamine, MMP-9, and proinflammatory cytokines amplify the progression of skin inflammation, tissue remodeling, and angiogenesis (Coussens *et al.*, 2000). Chymase, an MC-specific protease, can not only activate pro-MMP-9 and other MMP cascades (Tchougounova *et al.*, 2005) but can also inhibit enzyme degradation by TIMP-1, further stabilizing MMP-9. From our observations of the mouse model of rosacea, we have proven that proinflammatory peptides generated from epidermal keratinocytes and sensory nerve endings activate dermal MCs, which in turn amplify skin inflammation and angiogenesis via their secretion of proteases, MMP-9, and proinflammatory cytokines. In addition, our *in vitro* data of NHEK cells

strongly support the hypothesis that protease generated from MCs will induce dermal inflammation and increase the production of enzymes from the epidermal layer able to generate LL-37, with the result of creating a proinflammatory loop (Figure 3d and e). The release of MC proteases activates MMP-9 and KLKs in NHEKs, which results in the generation of additional active Cath LL-37 peptide.

In conclusion, rosacea features cannot be generated in mouse skin in the absence of MCs or when MCs have been pharmacologically stabilized. LL-37 and NPs activate MCs; activated huMCs, in turn, increase NHK expression and processing of LL-37, making huMCs central in amplifying rosacea inflammation and symptoms, especially erythema, flushing, and telangiectasia. Moreover, our preliminary results from a limited clinical trial supports the hypothesis that MC stabilizers can change metalloproteinase activity in rosacea in humans. On the basis of these observations, MC stabilizers should be considered as a future therapy in the treatment and prevention of rosacea symptoms.

MATERIALS AND METHODS

Reagents

Mca-Lys-Pro-Leu-Gly-Leu-Dpa-Ala-Arg-NH₂ fluorogenic substrate and 6-Amidino-2-naphthyl-4-guanidinobenzoate dimethanesulfonate were purchased from Enzo Life Sciences (Plymouth Meeting, PA). Cromolyn sodium and substance P fragment were purchased from Sigma-Aldrich (St Louis, MO). Adrenomedullin-2 and PACAP were purchased from AnaSpec (Fremont, CA). 4-methylumbelliferyl-2-acetamide-2-deoxy-b-D-glucopyranoside was purchased from Calbiochem (EMD Millipore; Billerica, MA). MMP-9-specific inhibitor I, chymotrypsin-specific fluorogenic substrate, and Pierce BCA protein assay kit were purchased from Thermo Fisher Scientific (Chicago, IL).

Human specimens

All the procedures involving human subjects were approved by the University of California San Diego Institutional Review Board under IRB number 071032 in accordance with adherence to the Helsinki Guidelines, and written informed patient consent was obtained. Skin biopsies (2 mm) were taken from the faces of healthy and rosacea subjects, as well as tape strips from the face of erythematotelangiectatic rosacea subjects in the dermatology clinic at the University of California, San Diego. Ten randomized adults with erythematotelangiectatic rosacea were applied a water-based solution containing either 4% cromolyn sodium or placebo, topically to their face twice a day, for 8 weeks. A clinical evaluation was performed at each visit. A total of six tape strips were obtained from right and left cheek at each of the first visit and the final visit. Facial erythema was clinically assessed by a blind investigator using the CEA, which grades erythema on a five-point scale: 0 = none (no redness), 1 = mild (slight pinkness), 2 = moderate (definite redness), 3 = significant (marked erythema), and 4 = severe (fiery redness). At each visit, the CEA was performed on five different facial regions: right cheek, left cheek, nose, chin, and glabella. The subject's final CEA score for each visit was calculated by summing the CEA score of each of the five facial regions for that visit.

Mouse experiments

B6.Cg-Kit^{W-sh}/HNIhrJaeBsmJ MC-deficient mice were bred at our facility. Institutional Animal Care and Use Committee (IACUC) of

UC San Diego approved all animal experiments. B6.Cg-Kit^{W-sh}/HNIhrJaeBsmJ (KitW-sh) the W-sash (Wsh) inversion mutation have MC deficiency, but lack anemia and sterility. Adult KitW-sh mice had a profound deficiency in MCs in all tissues examined but normal levels of major classes of other differentiated lymphoid cells. MC-deficient mice and WT mice (C57BL/6) were used for these experiments. WT- and MC-deficient mice were shaved 24 hours before intradermal injection with 50 μ l of 50 μ M or 320 μ M Cath LL-37 or filtered PBS ($n=3$) twice a day for 2 days. Skin biopsies were taken after 72 hours of observation, and tissues were immersed immediately into RNA stabilization reagent (RNAlater; QIAGEN science, Germantown, MD). Total RNA was extracted and purified using the RNeasy Mini Kit (QIAGEN science). mRNA expressions of proteases and cytokines were assessed by reverse transcriptase-PCR (RT-PCR). For the time-course observation of chymase and tryptase mRNAs, skin biopsies of WT and MC-deficient mice were taken at 1, 4, and 24 hours after Cath LL-37 injection and analyzed by RT-PCR.

For the neuropeptide challenge experiment, 0.1 μ M neuropeptide or PBS was injected into WT mice and MC-deficient mice intradermally. Skin biopsies were taken 6 hours after injection and analyzed by RT-PCR.

For the MC stabilizer experiment, cromolyn sodium (10 mg kg⁻¹ body weight, per day) (Sigma-Aldrich) was diluted in filtered PBS and injected intraperitoneally into WT mice for 4 days. After 4 days of treatment, 50 μ l of 320 μ M Cath LL-37 or PBS was injected intradermally twice a day for 2 days while continuing daily cromolyn treatment. At 72 hours after the beginning of the Cath LL-37 injections, skin biopsies were taken and analyzed for mRNA expression and protease activity.

MCs

Primary MCs were generated from mouse bone marrow and cultured in RPMI 1640 medium (Thermo Fisher Scientific) supplemented with 10% inactivated fetal bovine serum (Thermo Fisher Scientific), 25 mM HEPES (pH 7.4), 4 mM L-glutamine, 0.1 mM nonessential amino acids, 1 mM sodium pyruvate, 50 mM 2-ME, 100 IU ml⁻¹ penicillin, and 100 mg ml⁻¹ streptomycin, recombinant murine IL-3 (R&D Systems, Minneapolis, MN), and recombinant murine stem cell factor (R&D Systems). MMCs derived from bone marrow cells that are cultured with stem cell factor and IL-3 become mature *in vitro*. After 4 weeks, MCs were consistently generated, as confirmed by the expression of CD117 (c-Kit) and Fc ϵ RI. Cell maturation was confirmed by meta-chromatic staining with toluidine blue. The purity of MCs was greater than 98%. MCs were cultured in Stemline II Hematopoietic Stem Cell Expansion Medium (Sigma-Aldrich).

BMMC reconstitution in KitW-sh mice

4×10^6 Cells of C57BL/6 mature BMMCs were diluted in filtered PBS and injected into the shaved back skin of 6-week-old C57BL/6-KitW-sh mice (400 μ l; $8 \times 50 \mu$ l injections) intradermally. After 6 weeks, MCs were confirmed as resident cells in skin by toluidine blue staining.

Measurement of protease activity

MMP activities were determined in 0.1 M Tris-HCl (pH 7.5) containing 150 mM NaCl, 10 mM CaCl₂, 0.1 mM ZnCl₂, 0.05% (v/v) Brij35, and 0.1% (w/v) PEG6000. Protein extracts were normalized with a BCA assay kit. Total-MMP activity was determined by adding total-MMP fluorogenic substrate (5 μ M) Mca-Lys-Pro-Leu-Gly-Leu-Dpa-Ala-

Arg-NH₂ (Enzo Life Sciences) to protein extracts, incubating for 2 hours at 37°C, and subsequently measuring the activity (V_{max} per second) at a fluorescence excitation wavelength of 328 nm and an emission wavelength of 400 nm in a fluorescence plate reader (Gemini EM microplate spectrofluorometer; Molecular Devices, Sunnyvale, CA). To determine MMP-9 activity, MMP-9-specific inhibitor I (Thermo Fisher Scientific) was added to protein extracts. Chymase and tryptase activities were assayed in 0.1 mM Tris-HCl (pH 8.0) and 200 mM NaCl. Chymase activity was monitored by adding chymotrypsin-specific fluorogenic substrate (Thermo Fisher Scientific; 5 μM) to protein extracts, incubating for 2 hours at 37°C, and subsequently measuring the activity (V_{max} per second) at a fluorescence excitation wavelength of 380 nm and an emission wavelength of 460 nm. Tryptase activity was determined by adding serine protease-specific fluorogenic substrate (Boc-Phe-Ser-Arg-AMC, Bachem Bioscience, Torrance, CA) (5 μM) with/without ABESF (Sigma) to protein extracts, incubating for 2 hours at 37°C, and subsequently measuring relative fluorescence units at a fluorescence excitation wavelength of 354 nm and an emission wavelength of 422 nm. Proteins in skin tissues or cells were normalized with the Pierce BCA protein assay kit (Thermo Fisher Scientific).

Semiquantitative real-time PCR

cDNA was synthesized from RNA using the iScript cDNA Synthesis Kit (BioRad, Hercules, CA) according to the manufacturer's protocol. Synthesized cDNA was normalized using a NanoDrop spectrophotometer (Thermo Fisher Scientific). TaqMan Gene Expression Assays (Applied Biosystems ABI, Foster City, CA) were used to analyze the expressions of human *MMP9*, human *CMA1*, human *CAMP*, mouse *Mmp9*, mouse *Mmp1a*, mouse *Klk5*, mouse *Klk6*, mouse *Tpsab1*, mouse *Cma1*, mouse *Cxcl2*, and mouse *Tnf*, according to the manufacturer's instructions (Applied Biosystems). *GAPDH* and *Gapdh* mRNA were used as an internal control to validate RNA for each sample. mRNA expression was calculated as the relative expression to *GAPDH* or *Gapdh* mRNA, and all data are presented as fold change of each control.

MC degranulation assay

Degranulation percentage was assessed by measuring the activity of β-hexosaminidase in the supernatants of 1×10^5 MCs in 200 μl of Tyrode's buffer incubated for 1 hour with 0 or 20 nM Cath LL-37, 1% Triton X-100, and 10 μg ml⁻¹ compound 48/80 (Sigma-Aldrich) as a positive control. For each sample assayed, supernatant aliquots (25 μl) were mixed with substrate solution (50 μl), which consisted of 10 mM 4-methylumbelliferyl-2-acetamide-2-deoxy-β-D-glucopyranoside (Calbiochem) in 0.1 M sodium citrate buffer (pH 4.5), and were incubated for 30 min at 37°C. The reaction was then stopped by adding 50 μl of 0.4 M glycine (pH 10.7). The reaction mixtures were excited at 365 nm and measured at 460 nm in a fluorescence plate reader (Gemini EM microplate spectrofluorometer; Molecular Devices). To determine the total cellular content of this enzyme, an equivalent number of cells were lysed with 1% Triton X-100 and 10 μg ml⁻¹ compound 48/80 (Sigma-Aldrich). The release of β-hexosaminidase was calculated as the percentage of the total enzyme content.

Cath LL-37 stimulation of mMCs

mMCs were challenged *in vitro* with 10 μg ml⁻¹ Cath LL-37. The cells were harvested at 0, 5, and 24 hours, and mRNA was extracted

and assessed by RT-PCR for mouse metalloprotease 9 (*Mmp9*), mouse Chymase (*Cma1*), and mouse Tryptase (*Tpsab1*) expression. mMC metalloprotease activity was assessed at 6 and 24 hours after Cath LL-37 challenge, as previously described. mMC degranulation in response to LL-37 was assessed at 24 hours by β-hexosaminidase release, as described; positive control (48/80) and negative control (PBS) were added. For IL-6-level evaluation, mMCs were treated with 20 and 40 nM LL-37 for 24 and 48 hours. ELISA (ELISA MAX Deluxe; BioLegend, San Diego, CA) was used to determine mouse IL-6 in all supernatants of cell culture medium according to the manufacturer's instructions. All supernatant samples were normalized by the Pierce BCA protein assay kit (Thermo Fisher Scientific) to total protein content of the sample.

MC supernatant-NHEK stimulation

At 2 days after confluence in Epilife medium (Thermo Fisher Scientific) with 0.06 mM CaCl₂, NHEK cells were stimulated with supernatant from degranulated human cord blood-derived MCs in saline buffer, or saline buffer alone. MMP and KLK protease activities in the NHEKs were evaluated after 24 hours. RT-PCR was evaluated after 6 hours from the MC supernatant addition. For RT-PCR Cath LL-37 mRNA (*CAMP*) expression, 100 nM 1,25(OH)₂VD₃ was added. All of the experiments were repeated at least three times.

Fluorescence immunohistochemistry

Mouse skin frozen sections were fixed with acetone, washed in 1X PBS, blocked with 5% goat serum/1% BSA for 30 minutes, and incubated with anti-MMP-9 polyclonal antibody (ABBIOTEC, San Diego, CA) as a primary antibody (diluted 1:200). FITC-conjugated goat antibody to rabbit IgG (Molecular Probes, Grand Island, NY) was used as a secondary antibody (diluted 1:1,000) and was incubated for 40 minutes. For FcεRI detection, we used anti-mouse FcεRI PE (eBioscience, San Diego, CA). We mounted sections in ProLong Anti-Fade reagent (Molecular Probes) with 4', 6-diamidino-2-phenylindole. After overnight incubation at 4°C in the dark, images were obtained using a Zeiss LSM510 laser scanning confocal microscope coupled with an Axiovert 100 inverted-stage microscope.

Statistical analyses

The data are presented as means ± SEM. To determine the significance between two or more groups, one-way and two-way analysis of variance or the two-tailed *t*-test was used and analyzed by GraphPad Prism4 (GraphPad Software, La Jolla, CA). For all statistical tests, *P* < 0.05 was considered statistically significant.

CONFLICT OF INTEREST

The authors state no conflict of interest.

ACKNOWLEDGMENTS

We thank S. Brian Jiang (Division of Dermatology, Department of Medicine, University of California, San Diego) for providing healthy skin specimens and Amy Sullivan for helping in revising the manuscript. This work was supported by NIH grant R01 AI093957-01 and by the National Rosacea Society Grant.
